```
C(s) = K_2 \frac{s - z_c}{s - p_c}. (1)
            We will "arbitrarily" choose either p_c or z_c and
            the phase criterion for our design point \boldsymbol{\psi} will
            set the other. However, the "arbitrary" selection
            of p_c or z_c in fact affects both the transient
            response and the steady-state error (if it is
            finite).
            Let's work out the details. A way to approach
            designing a controller for a plant G with lead
            \underline{\text{compensator } C} \text{ is to consider the compensator} \\
            effects on the phase criterion, which must
            always be satisfied at points on the root locus:
                               \angle(G(s)C(s)) = \pi.
            In order for a desired point s = \psi to be on the
            root locus, then,<sup>7</sup>
                                                                        7. The 2\pi modulo in these expressions is suppressed for clarity.
                             \angle(G(\psi)C(\psi)) = \pi
                          \angle G(\psi) + \angle C(\psi) = \pi \Rightarrow
                                     \angle C(\psi) = \pi - \angle G(\psi) \Rightarrow
                   \angle(\psi - z_c) - \angle(\psi - p_c) = \pi - \angle G(\psi). = \Theta_c
            Let this angle \angle(\psi - z_c) - \angle(\psi - p_c), called the
            compensator angle, be given the symbol
                         \theta_{\rm c} \equiv \angle(\psi - z_{\rm c}) - \angle(\psi - p_{\rm c}).
            So we can choose to arbitrarily set the location
            of either z_c or p_c and the other will be set by the
            phase criterion. Therefore we have either
                      \angle(\psi-p_c) = \underbrace{\angle(\psi-z_c)}_{arbitrary} - \theta_c \quad or \quad
                      \angle(\psi-z_c) = \theta_c - \underbrace{\angle(\psi-p_c)}_{\text{arbitrary}}.
            And, from trigonometry,
             \mathfrak{p}_c = \mathrm{Re}(\psi) - |\mathrm{Im}(\psi)|/\tan(\theta_c - \angle(\psi - z_c)) \quad or \quad
             z_c = \text{Re}(\psi) - |\text{Im}(\psi)| / \tan(\theta_c + \angle(\psi - p_c)). (5b)
            This result is to be used in the design procedure
            that follows.
            Design procedure
            The following procedure provides a
            starting-point for proportional-lead controller
            design. Let's assume the transient response
            requirement is such that, according to the
            second-order approximation, we desire a
            closed-loop pole to be located at \underline{s} = \underline{\psi}.
               1. Design a proportional controller to meet
                   transient response requirements by
                   choosing the gain K_1 for the dominant
                   closed-loop poles to be as close as possible
               2. Include a cascade lead compensator of the
                   where we arbitrarily set either z_c or p_c;
                   initially, K_2=1. The other parameter must
                   be chosen to satisfy Eq. 5a or Eq. 5b. For
                   convenience, we repeat the key formulas:
                   \theta_c = \pi - \angle G(\psi) and, after setting arbitrarily z_c or p_c,
                   p_c = \mathrm{Re}(\psi) - |\mathrm{Im}(\psi)|/\tan(\angle(\psi-z_c) - \,\theta_c) \quad or \quad
               z_c = \operatorname{Re}(\psi) - |\operatorname{Im}(\psi)|/\tan(\theta_c + \angle(\psi - \mathfrak{v}_c)).
3. By construction \psi is on the root locus, so
                   the gain can be computed directly from
                   Eq. 2:
                                K_2 = \frac{1}{|K_1C(\psi)G(\psi)|}.
               4. Construct the closed-loop transfer
                   function with the controller
                                     K_1K_2\frac{s-z_c}{s-p_c}
               5. Simulate the time response to see if it
                   meets specifications. Tune.
            A design example
            Let a system have plant transfer function
                                     37500
                     \overline{s^4 + 70s^3 + 1625s^2 + 14000s + 37500}.
            Design a P-lead controller such that the
            closed-loop settling time is about 0.4 seconds
            and the overshoot is about 10%.
            Determining ψ
            We use Matlab for the design.8 First, we must
            determine \ what \ the \ specified \ transient \ response \\ \qquad \text{8. See ricopic.one/control/source/plead\_controller\_design\_example.m}
            criteria imply for the locations of our
            closed-loop poles. Let one of these desired pole
            locations be called \psi. The transient response
            performance criteria are as follows.
             Ts = .4; % sec ... spec settling time
             OS = 10; % percent ... spec overshoot
            The second-order approximation from
            Chapter trans tells us that the settling time
            specification implies a specific \mathrm{Re}(\psi) and the
            overshoot a specific angle \angle \psi. From previous
            results, the desired pole location \boldsymbol{\psi} (assuming
            the second-order approximation is valid) is
            given by the expression
                       \psi = -\frac{4}{T_s} \left(1 - j \frac{\pi}{\ln(100/\%OS)}\right). \label{eq:psi}
                   Figure PLead.1: root locus without compensation.
            This formula holds beyond the scope of this
            problem. We define it as an anonymous
            function.
             psi_fun = @(Ts,pOS) -4/Ts*(1-1j*pi/log(100/pOS));
            psi = psi_fun(Ts,0S);
disp(sprintf('psi = %0.3g + j %0.3g',real(psi),imag(psi)))
            psi = -10 + j 13.6
            P control
            We design a proportional controller that gets us
            as close as possible to \psi. The root locus is
            shown in Figure PLead.1.
            G = tf([37500],[1,70,1625,14000,37500]);
             figure
             rlocus(G)
            Although we cannot get close to \boldsymbol{\psi} on the root
            locus, we can at least meet our %OS
            specification by choosing a gain of about
                                   K_1 = 1.1.
            Let's construct the compensator and
            corresponding closed-loop transfer function \mathsf{G}_\mathsf{P}
            for gain control.
            K_1 = 1.1;
G_P = feedback(K_1*G,1);
            Lead compensation
            Now, we use cascade derivative compensation
            with compensator
            For now, we set K_2=1. Let's also set
            p_c = -40, -100, \text{ and } -400 to see how we fair
            with different "arbitrary" choices. From Eq. 5b,
            we compute the compensator zero
            \theta_c = \pi - \angle \mathsf{G}(\psi) \quad \text{and} \quad z_c = \mathrm{Re}(\psi) - |\mathrm{Im}(\psi)| / \tan(\theta_c + \angle(\psi - \mathfrak{p}_c)).
            p_c = [-40,-100,-400];
          theta_c = pi - angle(evalfr(G,psi));
          theta_p_c = angle(psi*ones(size(p_c))-p_c);
          z_c = real(psi) - abs(imag(psi))./tan(theta_c + theta_p_c);
             disp(sprintf('theta_c = %0.3g deg',rad2deg(theta_c)))
             for i = 1:length(p_c)
               disp(sprintf(...
                 'pole phase contribution = %0.3g deg',...
rad2deg(theta_p_c(i))...
               disp(sprintf('z_c = \%0.3g',z_c(i)))
                                                                ∠ ((4) G(4) = 1 = 180°
             theta_c = 96.7 deg
pole phase contribution = 24.5 deg z_c = -1.75
pole phase contribution = 8.62 deg
z_c = -6.26
pole phase contribution = 2 deg z_c = -7.91
            By construction, \boldsymbol{\psi} is on the root locus, so we
            can find K_2 directly from Eq. 2.
             C_sans = stack(1,tf(1,1)); % initialize model array
             C = stack(1,tf(1,1)); % initialize model array
             for i = 1:length(p_c)
C_sans(i) = zpk(z_c(i),p_c(i),1); % without gain
               K_2(i) = 1/abs(evalfr(K_1*C_sans(i)*G,psi));
               C(i) = K_1*K_2(i)*C_sans(i);
               disp(sprintf('K_2 = \%0.3g', K_2(i)))
            K_2 = 4.88
            K_2 = 15.2
            K_2 = 66.7
            Let's compute the closed-loop controller C<sub>lead</sub>,
            and the closed-loop transfer function G_{\text{lead}}.
             G_Plead = stack(1,tf(1,1));
             for i = 1:length(p_c)
  G_Plead(i) = feedback(C(i)*G,1);
            Simulate
            Our placement of the \boldsymbol{\psi} depended on the
            second-order approximation's accuracy, which
            in this case is questionable. In any case, we
            simulate the step response to test the efficacy of
            the P-lead controller design and to compare it
            with the P controller.
             t_a = linspace(0,2.5,200); % s ... sim time
             y_P = step(G_P,t_a); % P controlled step response
             for i = 1:length(p_c)
              y_Plead(:,i) = step(G_Plead(i),t_a); % P-lead step resp.
             figure
             plot(t_a,y_P);
             for i = 1:length(p_c)
               plot(t_a,y_Plead(:,i));
             xlabel('time (s)');
             ylabel('step response');
             grid on
              legend(..
                'P control', 'P-lead 1', 'P-lead 2', 'P-lead 3',...
               'location','southeast'...
```

rldesign.PLead Proportional-lead design

Similar to how proportional-lag controllers can

controllers, proportional-lead controllers can be considered passively realizable PD controllers. The idea is to choose a design point ψ through which we construct the root locus to pass. As with PD control, this point is chosen to meet primarily transient response characteristics, and the controller contributes the proper phase such that the root locus passes through the point; however, we have both a pole and a zero to set

be considered passively realizable PI

in the compensator:

disp(sprintf('settling time: %0.3g',si_P.SettlingTime))
disp(sprintf('percent overshoot: %0.3g\n',si_P.Overshoot))
for i = 1:length(p_c)
si_Plead = stepinfo(y_Plead(:,i),t_a);
disp(sprintf('p_c: %0.3g',p_c(i)))
disp(sprintf(...
'settling time: %0.3g',si_Plead.SettlingTime ...

0.5

45

disp('P control')
si_P = stepinfo(y_P,t_a);

The responses, shown in Figure PLead.2, suggest the lead-compensated controllers are at

specifications. The steady-state error is worse for compensator locations that are less-negative and better for those that are more-negative. For this reason, we remember that our "arbitrary" choice of one of our compensator parameters still affects the steady-state (and sometimes transient) response. Let's use stepinfo to

disp(sprintf(... 'percent overshoot: %0.3g\n',si_Plead.Overshoot. P control settling time: 0.906 percent overshoot: 13.6 p_c: -40 settling time: 1.28 percent overshoot: 66.2 p_c: -100 settling time: 0.371 percent overshoot: 6.95 p_c: -400 settling time: 0.37 percent overshoot: 7.31 We see that most of the P-lead controllers meet the settling time and percent overshoot requirements. However, the first one is problematic. This is mostly due to the second-order approximation being significantly violated in this case. We see from the time response that the initial overshoot happens quickly, but the return to steady-state is slow. If desired, the gain K_2 and compensator pole and

zero locations could be tuned, iteratively.
