# 01.3 A CPU programming model

A central processing unit (CPU) has three functions that are repeated endlessly:

- 1. fetch an instruction from memory,
- 2. translate the instruction, and
- 3. execute it.

Typically, the control unit of a CPU fetches instructions from memory and translates them. It then sends to the datapath of the CPU to be processed. It does this by means of registers, which are small, special purpose units of memory in the datapath.

## Core ARM registers

A developer of an embedded system with a given CPU must understand it at the "application-level," which is distinguished from the "system-level" of the operating system. An application-level "view" of the ARM processor registers has thirteen general-purpose 32-bit registers named R0-R12 and three special-purpose registers named SP, LR, and PC (also called R13-R15) (ARM, 2014, p. A2-45). The stack pointer SP (R13) register contains the memory address of, and therefore points to, the top of the active stack. A stack holds data, such as "automatic variables," temporarily. We'll talk more about stacks, later. The return link LR (R14) register is used, for instance, to store the current memory address of the calling program during a subroutine call. The program counter PC (R15) register contains the memory address of the current instruction plus eight (bytes)—that is, of two instructions-from-now.<sup>4</sup> The general-purpose registers typically hold

data, such as ints, doubles, and chars.

4. For an interesting discussion of "why the offset," see this informative SO answer.

## Other ARM registers

The 32-bit application status register (APSR) stores the program's last-executed instruction return status in flags:

- N: negative condition (e.g. two's complement negative MSbit),
- Z: zero condition (e.g. equal from comparison),
- C: carry condition (e.g. unsigned overflow from addition),
- V: overflow condition (e.g. signed overflow from addition), and
- Q: overflow or saturation condition (e.g. from DSP)

encoded as single bits. These flags can be tested by the next instruction for conditional execution. A nibble of the APSR stores the GE: greater-than or equal flag.

The execution state registers allows special instruction sets, such as Thumb, to be executed; contains special Thumb instructions; and sets the register endianness mapping (big-endian or little-endian).

The Xilinx Z-7010 Coretex-A9 has the optional ARMv7-A vector floating-point unit VFPv3 ISA extension, which enables high-performance and efficiency of floating-point arithmetic. The extension has its own, dedicated extension registers.

## Types of instructions

Below are some examples of the types of instructions a CPU might encounter:

- load or store (to/from CPU registers),
- transfers (between registers),
- move (memory  $\rightarrow$  memory),
- set/reset bits,
- shift/rotate,

- arithmetic (add, subtract, multiply, divide, negate),
- logic (ands, ors, etc.),
- conditional branches and jumps,
- unconditional branches and jumps, and
- subroutines.

### Addressing modes

Addressing modes specify how the CPU is to calculate the memory address for a load or a store operation. For the ARMv7-A ISA, the address is composed of two parts: a base register value and an offset (ARM, 2014, p. A4-176). The base register can be any core ARM register. The offset must have one of the following three formats.

- **Immediate** An unsigned number, it can be summed with (or subtracted from) the value of the base register.
- **Register** A value from a core ARM register other than PC.
- **Scaled register** A shifted value from a core ARM register other than PC summed with (or subtracted from) the value of the base register.

These lead to the following three addressing modes:

- **Offset** The offset is summed with (or subtracted from) the base register, forming the memory address.
- **Pre-indexed** Same as "Offset," followed by the new address is then assigned to the base register.
- **Post-indexed** The memory address is the value of the base register. Then the base register is offset.
